Observation of charmless hadronic B decays

The ALEPH Collaboration

Abstract

Four candidates for charmless hadronic B decay are observed in a data sample of four million hadronic Z decays recorded by the ALEPH detector at LEP. The probability that these events come from background sources is estimated to be less than 10^{-6} . The average branching ratio of weakly decaying B hadrons (a mixture of B_d^0 , B_s^0 and Λ_b weighted by their production cross sections and lifetimes, here denoted B) into two long-lived charged hadrons (pions, kaons or protons) is measured to be $Br(B \rightarrow h^+h^-) = (1.7_{-0.7}^{+1.0} \pm 0.2) \times 10^{-5}$. The relative branching fraction $(Br(B_d^0 \rightarrow \pi^+\pi^-) + r_s Br(B_s^0 \rightarrow \pi^+K^-)) / (Br(B_d^0 \rightarrow h^+h^-) + r_s Br(B_s^0 \rightarrow h^+h^-))$, where r_s is the ratio of B_s^0 to B_d^0 decays in the sample, is measured to be $1.0_{-0.3}^{+0.0}{}_{-0.1}^{+0.0}$. In addition, branching ratio upper limits are obtained for a variety of exclusive charmless hadronic two-body decays of B hadrons.

1 Introduction

Decays of B hadrons into final states which do not contain a charm quark can proceed either via a tree-level $b \rightarrow u$ transition or through one-loop penguin diagrams. For the decay¹ $B_d^0 \rightarrow \pi^+\pi^-$, the contribution coming from $b \rightarrow u$ transitions is expected to dominate [1]. The contribution originating from penguin diagrams is believed to be more important for the decay $B_d^0 \rightarrow K^+\pi^-$ [2]. The decay $B_d^0 \rightarrow \pi^+\pi^-$ is of particular interest since it is expected to play an important role in future studies of CP violation in the b system [3]. The interpretation of such studies depends on the branching ratios for the channels $B_d^0 \rightarrow \pi^+\pi^-$ and $B_d^0 \rightarrow K^+\pi^-$ as well as on the relative contributions of the $b \rightarrow u$ and penguin amplitudes.

The CLEO collaboration has found the first evidence for charmless hadronic B decays [4]. They measure a combined branching ratio $\mathcal{B}r(B_d^0 \rightarrow \pi^+\pi^- + K^+\pi^-) = (1.8_{-0.5}^{+0.6} {}_{-0.3}^{+0.2} \pm 0.2) \times 10^{-5}$ but are unable to obtain statistically significant signals in the two individual channels. Searches for such processes have recently been undertaken at LEP, where the B hadrons are heavily boosted and their decay products originate from distinct secondary vertices. This feature, when exploited by the use of high precision vertex detectors, allows an effective tagging of the decay products of the B hadrons. The OPAL collaboration has set branching ratio upper limits on a variety of two-body final states [5]. The DELPHI collaboration has observed five candidate events of the type $B \rightarrow h^+h^-$ [6]. In the ALEPH data sample of four million hadronic Z decays, collected between 1991 and 1995, the CLEO measurements would predict the production of approximately 13 decays of the type $B_d^0 \rightarrow \pi^+\pi^-, K^+\pi^-$. At LEP it is also possible to look for the corresponding charmless decays of both B_s^0 and Λ_b .

2 The ALEPH detector

The ALEPH detector and its performance are described in detail elsewhere [7, 8] and only a brief description is given here.

A high resolution vertex detector (VDET) consisting of two layers of double-sided silicon microstrip detectors surrounds the beam pipe. The inner layer is at an average radius of 6.5 cm from the beam axis and covers 85% of the solid angle, while the outer layer is at an average radius of 11.3 cm and covers 69%. The spatial resolution for the $r\phi$ and z projections (transverse to and along the beam direction, respectively) is $12 \mu\text{m}$ at normal incidence. The vertex detector is surrounded by a drift chamber with eight axial wire layers and a time projection chamber (TPC) that measures up to 21 three-dimensional points per track. These detectors are immersed in an axial magnetic field of 1.5 T and together provide a momentum resolution of $\sigma_p/p = 0.0006p \oplus 0.005$ (p in GeV/c). For tracks with hits in both layers of the VDET, the impact parameter resolution may be parameterized as $\sigma_\delta = 25 \mu\text{m} + 95 \mu\text{m}/p$ (p in GeV/c) in both the $r\phi$ and rz views. The TPC also provides up to 338 measurements of the specific ionization of a charged particle (dE/dx). An average K/π separation of approximately two standard deviations is achieved for charged tracks with at least 50 dE/dx measurements and momenta greater than $3 \text{ GeV}/c$. The dE/dx measurements are expressed as the difference between the measured and expected specific energy loss in units of standard deviations for a given particle mass hypothesis.

This tracking system is surrounded by a lead/wire-plane sampling calorimeter which is used to measure electromagnetic energy and to identify electrons and photons. The iron return yoke of

¹Throughout this paper charge conjugate modes are always implied.

the magnet is instrumented with streamer tubes to form a hadron calorimeter. It is surrounded by two additional double layers of streamer tubes which are used to provide muon identification.

3 Event selection

The selection of hadronic events is based on charged tracks and is described elsewhere [9]. For these events an interaction point is reconstructed on an event by event basis using the constraint of the beam axis position and the size of the luminous region [10]. This interaction point is determined with an average resolution of $85 \mu\text{m}$ for $b\bar{b}$ events, projected along the sphericity axis of the event. Charmless hadronic B decays are identified by looking for two oppositely charged particles, originating from a displaced vertex, with a mass above the kinematic limit for particles coming from B decays involving charm. Such decays are selected using a combination of cuts based on kinematics and vertex topology.

Kinematics:

- Each track is required to have a momentum above $3 \text{ GeV}/c$.
- The momentum of the B hadron candidate has to be at least $30 \text{ GeV}/c$.

Vertex topology:

- Each track is required to have at least one $r\phi$ coordinate and at least one z coordinate in the VDET.
- The three-dimensional impact parameter of each track has to be inconsistent with the interaction point by more than three standard deviations.
- Each track has to cross the flight path of the B hadron candidate downstream of the interaction point.
- The two tracks are required to form a vertex with a probability of at least 1%.
- This vertex has to be at least six standard deviations and at most 2 cm downstream of the interaction point.
- The B hadron candidate is required to point back from its vertex to the interaction point with a probability of at least 1%.

Additionally a track pair is rejected if either track is an identified lepton candidate [11].

Monte Carlo studies show that the maximum mass of two tracks coming from a B meson decay involving charm and passing the above kinematic cuts, with each track assigned the pion mass, is approximately $4.8 \text{ GeV}/c^2$. The corresponding limit from B baryon decays involving charm is $5.0 \text{ GeV}/c^2$. A signal region is defined by requiring that: (i) the mass of the two tracks, under the pion hypothesis, be at least three standard deviations above $5 \text{ GeV}/c^2$ and (ii) the mass of the two tracks be less than three standard deviations above the Λ_b mass [12] when one track is given the proton hypothesis. The average resolution on the measured mass obtained from a sample of $B_d^0 \rightarrow \pi^+\pi^-$ Monte Carlo events is $44 \text{ MeV}/c^2$. The resolution on the measured B hadron mass is studied in the data using a sample of cleanly reconstructed $J/\psi \rightarrow \mu^+\mu^-$ decays. A scale factor on the uncertainty on the mass of 1.20 ± 0.05 is estimated. This factor, which is applied to the mass

uncertainty estimated by the reconstruction program, is taken into account in the above selection and is included in any quoted mass uncertainties.

The efficiency of the above selection criteria was determined using Monte Carlo simulation to be $(21.0 \pm 0.6)\%$ for the decay $B_d^0 \rightarrow \pi^+ \pi^-$, and $(20.4 \pm 0.6)\%$ for the decay $\Lambda_b \rightarrow p \pi^-$. It is also possible for charmless hadronic B decays involving additional neutral particles to pass the above selection. The efficiency for one such decay, $B_d^0 \rightarrow \pi^\pm \rho^\mp$, was determined to be $(0.5 \pm 0.2)\%$.

4 Results

The above selection criteria were applied to a sample of four million hadronic Z decays. The mass distribution, under the pion hypothesis, is shown for both unlike-sign and like-sign pairs in Figure 1. In the unlike-sign pair sample there are four candidate events satisfying the selection criteria outlined above. Some relevant properties of these candidate events are given in Table 1. The four selected decays are all compatible with at least one two-body decay hypothesis $B \rightarrow h^+ h^-$. There is one additional event above $5 \text{ GeV}/c^2$, with a measured mass of $5.08 \pm 0.06 \text{ GeV}/c^2$ and therefore less than three standard deviations above $5 \text{ GeV}/c^2$. In this event there is 1.2 GeV of neutral electromagnetic energy near the B hadron candidate. If this energy deposition is interpreted as originating from a π^0 decay this event is consistent with a charmless hadronic B decay of the type $B_d^0 \rightarrow \pi^\pm \rho^\mp$. In the like-sign pair control sample there are no candidates with a mass, under the pion hypothesis, above $5 \text{ GeV}/c^2$. The four candidate events were investigated further to try and identify possible effects, such as pattern recognition mistakes, which could cause the vertex properties of the events to be mismeasured. No such problems were found. An event display of one of the four candidates is shown in Figure 2.

A background estimate for the above selection was obtained using a Monte Carlo sample of hadronic Z decays simulated without charmless B decays. Events were selected with slightly relaxed kinematic cuts at the generator level and were then passed through the full detector simulation and reconstruction. The ability of the Monte Carlo to reproduce accurately the level of background in the data was tested by removing some of the selection criteria. In particular, this was studied using like-sign track pairs which passed the kinematic cuts (with a relaxed momentum cut $P_B > 20 \text{ GeV}/c$), had at least one $r\phi$ coordinate and at least one z coordinate in the VDET and had a significant impact parameter. There should be no contribution from B hadron decays to these like-sign track pairs. In the mass region at least three standard deviations above 5.0 and below $6.5 \text{ GeV}/c^2$ there are 156 such track pairs observed in the data compared with a Monte Carlo prediction of 52 ± 6 . This underestimate of the background in the Monte Carlo, by a factor of three, remains when both tracks are further required to cross the flight path of the B hadron candidate downstream of the interaction point. The origin of this discrepancy is not fully understood, but a large fraction of it can be attributed to a previously observed excess of tracks with high transverse momentum relative to their jet axes observed in the data with respect to Monte Carlo predictions [13]. In the present analysis when only the kinematic cuts are applied the Monte Carlo underestimates the data by a factor of 1.6, which explains only a part of the effect. When normalised to the number of observed events, the Monte Carlo provides an adequate description of a variety of relevant variables for track pairs passing the relaxed selection (shown in Figure 3). Figure 3(a-c) indicates that the simulation provides an adequate description of the shape of both kinematic variables used in the selection and also of the tails of the impact parameter distribution. To study the flavour composition of the background the probability \mathcal{P}_{uds} that all tracks in the hemisphere opposite to the B hadron candidate originate from the interaction point

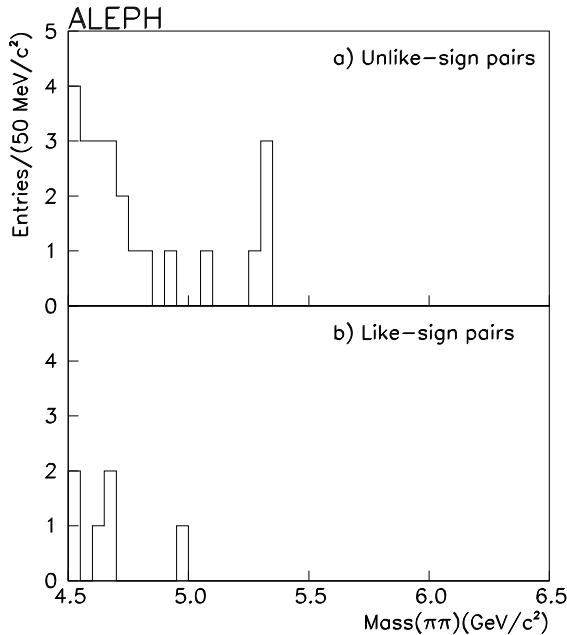

Figure 1: Mass distributions, under the pion hypothesis, for both (a) unlike-sign and (b) like-sign candidates.

was calculated [14]. From the distribution of \mathcal{P}_{uds} , shown in Figure 3(d), the relative proportion of background coming from B decays (which would preferentially have a low value of \mathcal{P}_{uds}) and from light quark decays is seen to be well reproduced by the Monte Carlo. (The values of \mathcal{P}_{uds} obtained for the four candidate events are given in Table 1. One event has a probability of 54%. The probability of at least one out of four simulated signal events having a probability of this value or larger is 12%.) To account for the above factor-of-three discrepancy, it is assumed that the probability to observe a background event in the data, after all selection criteria are applied, is three times higher than predicted by the Monte Carlo. It is further assumed that after the final cuts the background is flat in the above mass region, and that like-sign and unlike-sign background events are produced at equal rate. These final two assumptions are valid in data and Monte Carlo for the relaxed selection described above. A background estimate of 0.05 ± 0.02 was obtained from Monte Carlo simulation. To obtain sufficient statistics a preselection was applied at the generator level. This estimate takes into account the observed factor-of-three discrepancy in the background normalisation. The probability for observing four or more background events in the data in the signal region is less than 10^{-6} .

5 Branching ratio measurements

From the number of selected events, the average branching ratio of weakly decaying B hadrons into two long-lived charged hadrons (pions, kaons or protons) with no accompanying neutral particles is measured to be $\mathcal{B}r(B \rightarrow h^+h^-) = (1.7_{-0.7}^{+1.0} \pm 0.2) \times 10^{-5}$. This measurement assumes that corresponding decays of B_d^0 , B_s^0 and Λ_b have equal partial widths (*e.g.*, $\Gamma(B_d^0 \rightarrow \pi^+\pi^-) =$

Table 1: Some properties of the four candidate events. For reference the masses of the B_d^0 and B_s^0 mesons were taken as 5.279 ± 0.002 and 5.375 ± 0.006 GeV/c^2 , respectively (PDG94).

	Event a	Event b	Event c	Event d
B candidate momentum P_B (GeV/c)	38	40	35	39
Track momentum P^+ (GeV/c)	9	30	9	33
Track momentum P^- (GeV/c)	30	10	26	7

$\Gamma(B_s^0 \rightarrow \pi^+K^-) = \Gamma(\Lambda_b \rightarrow p\pi^-)$). The relevant ratios of branching ratios are obtained from this assumption on the partial widths by weighting with the measured lifetimes of the different B hadrons [15] and the fractions of B_d^0 , B_s^0 or Λ_b resulting from the hadronization of a b quark taken to be $(37.8 \pm 2.2)\%$, $(11.2 \pm 1.9)\%$ and $(13.2 \pm 4.1)\%$, respectively [16]. They are in agreement with theoretical expectations [2, 17].

The systematic uncertainty quoted on the measured branching fraction contains contributions from the various sources listed in Table 2. The uncertainties in the hadronization of b quarks into the different B hadrons and their measured lifetimes give a contribution of 2%. The combinatorial background contribution is estimated to be 1% based on the above Monte Carlo prediction of 0.05 events expected. The contribution of charmless hadronic decays involving additional neutral particles is estimated using the ratio of the efficiency estimates obtained for the channels $B_d^0 \rightarrow \pi^+\pi^-$ and $B_d^0 \rightarrow \pi^\pm\rho^\mp$. The branching ratio $\mathcal{B}r(B_d^0 \rightarrow \pi^\pm\rho^\mp)$ is taken to be three times greater than the branching ratio $\mathcal{B}r(B_d^0 \rightarrow \pi^+\pi^-)$, as expected from theoretical predictions [17]. The four selected decays have a mass inconsistent by more than three standard deviations with the $B_d^0 \rightarrow \pi^\pm\rho^\mp$ hypothesis. The b quark fragmentation function was varied within its experimental uncertainty [18] leading to a 3% change in efficiency. The ability of the Monte Carlo simulation

Figure 2: A fish-eye $r\phi$ view of the decay hemisphere and a close-up view of the interaction region for event b. The B hadron candidate tracks (h^+, h^-) form a consistent vertex (B), well displaced from the interaction point (IP). This vertex and the interaction point are indicated together with their three-standard-deviation error ellipses.

to correctly reproduce the efficiency of the vertex cuts was checked using a sample of cleanly reconstructed $J/\psi \rightarrow \mu^+ \mu^-$ decays. The number of selected decays where both tracks have at least one $r\phi$ coordinate and at least one z coordinate in the VDET, and form a consistent vertex, was measured to be $(3 \pm 4)\%$ higher in the data than in the Monte Carlo. The total systematic uncertainty is obtained by adding the contributions from the different sources in quadrature.

An unbinned maximum likelihood fit was performed on the selected event sample in order to extract the average branching ratio $B_d^0 \rightarrow \pi^+ \pi^-$, $B_s^0 \rightarrow \pi^+ K^-$ relative to all decays, $R = (\mathcal{B}r(B_d^0 \rightarrow \pi^+ \pi^-) + r_s \mathcal{B}r(B_s^0 \rightarrow \pi^+ K^-)) / (\mathcal{B}r(B_d^0 \rightarrow h^+ h^-) + r_s \mathcal{B}r(B_s^0 \rightarrow h^+ h^-))$, where r_s

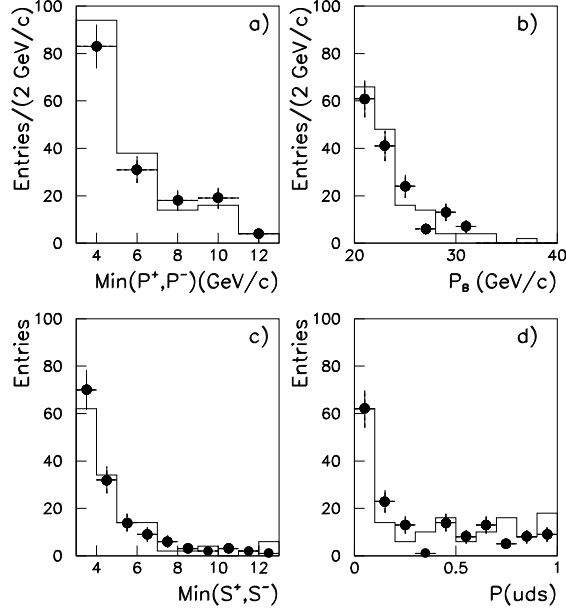

Figure 3: Comparisons between data (points with error bars) and Monte Carlo simulation, normalised to the number of data events (histogram), for the relaxed selection showing: (a) the smaller of the two individual track momenta (P^+, P^-); (b) the momentum P_B of the B hadron candidate; (c) the smaller of the two impact parameter significances of the track pair (S^+, S^-); (d) the probability \mathcal{P}_{uds} that all tracks in the hemisphere opposite to the B hadron candidate originate from the interaction point.

is the ratio of B_s^0 to B_d^0 decays in the sample. The likelihood is defined as

$$\mathcal{L}(R) = \prod_{i=1}^n [R \times (f_d \mathcal{P}(B_d^0 \rightarrow \pi^+ \pi^-) + 0.5 f_s (\mathcal{P}(B_s^0 \rightarrow \pi^+ K^-) + \mathcal{P}(\bar{B}_s^0 \rightarrow K^+ \pi^-))) + (1 - R) \times (0.5 f_d (\mathcal{P}(B_d^0 \rightarrow K^+ \pi^-) + \mathcal{P}(\bar{B}_d^0 \rightarrow \pi^+ K^-)) + f_s \mathcal{P}(B_s^0 \rightarrow K^+ K^-))],$$

where f_d and f_s are the fractions of B_d^0 and B_s^0 decays in the sample, respectively, and the probability density \mathcal{P} for any given hypothesis is the product of the three probability densities

corresponding to the mass and dE/dx measurements together with their respective uncertainties. The probability densities of the four candidate events, under various decay hypotheses, are given in Table 3. The fit has also been performed containing corresponding terms from Λ_b decays; however, for the four selected events the Λ_b hypothesis is very unlikely and these terms do not change the results. The fractions f_d and f_s were calculated assuming that $\Gamma(B_d^0 \rightarrow \pi^+\pi^-) = \Gamma(B_s^0 \rightarrow \pi^+K^-)$ and $\Gamma(B_d^0 \rightarrow K^+\pi^-) = \Gamma(B_s^0 \rightarrow K^+K^-)$ and taking into account the different lifetimes and hadronization factors as above. The fit also assumed that the contributions of other charmless B decays, such as $B_d^0 \rightarrow K^+K^-$ and $B_s^0 \rightarrow \pi^+\pi^-$, were negligible. The fit yielded

$$R = 1.0_{-0.3}^{+0.0} {}_{-0.1}^{+0.0},$$

where the statistical uncertainty quoted corresponds to a region containing 68.4% of the integrated likelihood. The value of R is greater than 0.4 with a 95% confidence level.

The sources of systematic uncertainty considered are given in Table 4. The uncertainties in the hadronization of b quarks into the different B hadrons and their measured lifetimes give a contribution of 2%. The effect of the small background contributions coming from the combinatorial and charmless neutral backgrounds is conservatively taken as maximal. The effects of the non-Gaussian tails on the mass and dE/dx measurements were studied in the data. The dE/dx distribution of muons in a selected sample of $J/\psi \rightarrow \mu^+\mu^-$ decays was fitted to a double Gaussian. The width of the second Gaussian was fixed to be twice that of the first. The fraction of tracks contained in the second Gaussian was measured to be $(2.5 \pm 2.0)\%$. For charmless B decays passing the above event selection, the uncertainty in the mass measurement is dominated by the contribution coming from the momentum measurement of the individual tracks. The non-Gaussian tails of the momentum resolution for high momentum tracks were studied in a sample of selected $Z \rightarrow \mu^+\mu^-$ decays. The study was restricted to the upper side of the distribution to minimize the effect of initial-state radiation. The fraction of tracks contained in a second Gaussian with double width was measured to be $(5.0 \pm 0.5)\%$. When the likelihood fit was repeated taking into account these non-Gaussian tails, the lower limit on R decreased by an amount corresponding

Table 5: Consistency of the candidate events with the different hypotheses expressed as a χ^2 probability \mathcal{P}_{χ^2} based on the mass and the dE/dx measurements of each track. Also shown are the 90% confidence level upper limits obtained for the branching ratios under these hypotheses.

Decay Hypothesis	Event a	Event b	Event c	Event d	90% Confidence Level BR Upper Limit
$B_d^0 \rightarrow \pi^+\pi^-$	0.71	0.08	0.87	0.07	4.1×10^{-5}
$B_d^0 \rightarrow K^+\pi^-$	0.06	0.36	0.04	0.08	3.0×10^{-5}
$B_d^0 \rightarrow K^+K^-$	< 0.01	< 0.01	< 0.01	< 0.01	1.8×10^{-5}
$B_d^0 \rightarrow p\bar{p}$	< 0.01	< 0.01	< 0.01	< 0.01	1.8×10^{-5}
$B_s^0 \rightarrow \pi^+\pi^-$	0.87	0.10	0.08	0.12	1.7×10^{-4}
$B_s^0 \rightarrow \pi^+K^-$	0.18	0.86	0.28	0.26	2.1×10^{-4}
$B_s^0 \rightarrow K^+K^-$	0.01	< 0.01	0.01	< 0.01	5.9×10^{-5}
$B_s^0 \rightarrow p\bar{p}$	< 0.01	< 0.01	< 0.01	< 0.01	5.9×10^{-5}
$\Lambda_b \rightarrow p\pi^-$	0.01	< 0.01	< 0.01	< 0.01	5.0×10^{-5}
$\Lambda_b \rightarrow pK^-$	< 0.01	< 0.01	< 0.01	< 0.01	5.0×10^{-5}

to a contribution added in quadrature of 6%. The total systematic uncertainty is obtained by adding the contributions from the different sources in quadrature.

6 Upper limits on exclusive final states

The selected event sample is also used to set upper limits for the branching ratios of exclusive charmless hadronic two-body decays of B hadrons. For each decay hypothesis a probability \mathcal{P}_{χ^2} is obtained from the measured mass of the system and the dE/dx values of the two tracks. From the total number of events consistent with each final state, having $\mathcal{P}_{\chi^2} > 10\%$, the 90% confidence level upper limits for the individual branching ratios are calculated and given in Table 5. This calculation assumes that $\Gamma(Z \rightarrow b\bar{b})/\Gamma(Z \rightarrow q\bar{q}) = 0.22$ and that the fractions of b quarks hadronizing into B_d^0 , B_s^0 and Λ_b are as given above. The cut on \mathcal{P}_{χ^2} was optimized to give the lowest average branching ratio upper limit for a sample of Monte Carlo experiments generated without signal production using the technique described in Ref. [19]. To be conservative no background subtraction is performed in deriving these upper limits. The branching ratio upper limits obtained are competitive with those obtained elsewhere [4, 5, 6] but are still at least a factor of two larger than theoretical expectations [1, 2, 17].

7 Conclusions

A search for charmless hadronic B decays has been performed in data recorded by the ALEPH detector at LEP. Four candidate events are observed in a sample of four million hadronic Z decays. The probability that these events come from background sources is estimated to be less than 10^{-6} . The average branching ratio of weakly decaying B hadrons into two long-lived charged hadrons (pions, kaons or protons), weighted by their production cross sections and lifetimes, is measured to be $\mathcal{B}r(B \rightarrow h^+h^-) = (1.7_{-0.7}^{+1.0} \pm 0.2) \times 10^{-5}$. The relative branching fraction $R = (\mathcal{B}r(B_d^0 \rightarrow \pi^+\pi^-) + r_s \mathcal{B}r(B_s^0 \rightarrow \pi^+K^-)) / (\mathcal{B}r(B_d^0 \rightarrow h^+h^-) + r_s \mathcal{B}r(B_s^0 \rightarrow h^+h^-))$, where r_s is the ratio of B_s^0 to B_d^0 decays in the sample, is measured from an unbinned maximum likelihood fit

to be $R = 1.0_{-0.3}^{+0.0} {}_{-0.1}^{+0.0}$. In addition, branching ratio upper limits of order 10^{-4} are obtained for a variety of exclusive charmless hadronic two-body decays of B hadrons.

8 Acknowledgements

We wish to thank our colleagues from the accelerator divisions for the successful operation of LEP. We are indebted to the engineers and technicians at CERN and our home institutes for their contribution to the good performance of ALEPH. Those of us from non-member countries thank CERN for its hospitality.
